There are limited national epidemiological data for community-associated (CA)-*Clostridium difficile* infections (CDIs). Between March 2011 and March 2013, laboratories in England submitted to the *Clostridium difficile* Ribotyping Network (CDRN) up to 10 diarrhoeal faecal samples from successive patients with CA-CDI, defined here as *C. difficile* toxin-positive diarrhoea commencing outside hospital (or less than 48 hours after hospital admission), including those cases associated with community-based residential care, with no discharge from hospital within the previous 12 weeks. Patient demographics and *C. difficile* PCR ribotypes were compared for CA-CDIs in our study and presumed healthcare-associated (HA) CDIs via CDRN. Ribotype diversity indices, ranking and relative prevalences were very similar in CA- vs HA-CDIs, although ribotypes 002 (p = 0.0001), 020 (p = 0.009) and 056 (p < 0.0001) predominated in CA-CDIs; ribotype 027 (p = 0.01) predominated in HA-CDIs. Epidemic ribotypes 027 and 078 predominated in institutional residents with CDI (including care/nursing homes) compared with people with CDI living at home. Ribotype diversity decreased with increasing age in HA-CDIs, but not in CA-CDIs. Ribotype 078 CA-CDIs were significantly more common in elderly people (3.4% (6/174) vs 8.7% (45/519) in those aged < 65 and ≥ 65 years, respectively; p = 0.019). No antibiotics were prescribed in the previous four weeks in about twofold more CA-CDI vs HAs (38.6% (129/334) vs 20.3% (1,226/6,028); p < 0.0001). We found very similar ribotype distributions in CA- and HA-CDIs, although a few ribotypes significantly predominated in one setting. These national data emphasise the close interplay between, and likely common reservoirs for, CDIs, particularly when epidemic strains are not dominant.

Methods

Community-associated *C. difficile* infection surveillance scheme

During March 2011 to March 2013, hospital microbiology laboratories in England were asked to send up to 10 faecal samples to their regional CDRN laboratory from successive CDI cases who met the definition of CA-CDI: *C. difficile* toxin-positive diarrhoea (loose stools with no clear medical/surgical explanation) with onset of symptoms while outside hospital (or within the first 48 hours of hospital admission), including those cases associated with community-based residential care, and antibiotic use [1]. There is, however, limited information on the epidemiology of community-associated (CA)-CDI, but data suggest that the incidence of CA-CDI could be increasing [2-4]. However, variation in reported rates may be due to varying definitions and case ascertainment bias as a consequence of suboptimal or incomplete testing of community-based patients [5]. In general, it is also known that there is marked underascertainment of the causes of diarrhoea in the community [6,7].

In conjunction with mandatory reporting of CDI cases in England [8], additional surveillance includes voluntary submission of faecal samples to a centrally funded scheme (Clostridium difficile Ribotyping Network (CDRN) for England and Northern Ireland), which has provided specific data on circulating *C. difficile* PCR ribotypes since 2007. CDRN now examines over a third of all reported CDI cases in England [9]. A better understanding of the epidemiology of CA-CDI is required in order to achieve improved prevention and control of cases. We have therefore augmented the national CDRN surveillance scheme to compare the patient demographics and *C. difficile* ribotypes associated with healthcare (HA)- and CA-CDI over a two-year period, March 2011 to March 2013.
those without discharge from hospital within the previous 12 weeks [10,11]. More than 90% of (about 150) laboratories were following national (two-stage testing) guidance for CDI diagnosis. All faecal samples submitted were accompanied by a brief patient-based questionnaire (anonymised) that was completed at the local microbiological testing laboratory. The questionnaire recorded demographic data, details of hospitalisation, residency in a care/nursing home, and antibiotic exposure (from patient records where available). Only the first half of the patient’s residential post code was collected to permit potential geographical mapping, while retaining anonymity. *Clostridium difficile* was cultured at the receiving CDRN laboratory. If the sample was *Clostridium difficile* culture-negative then another case was recruited prospectively. All *Clostridium difficile* isolates were centralised at the CDRN Reference Laboratory in Leeds, England, and referred to the UK Anaerobe Reference Unit (UKARU) in Cardiff, Wales, for PCR ribotyping. Demographic and typing data were analysed at the CDRN Reference laboratory, Leeds.

**C. difficile** culture, identification and PCR ribotyping

*C. difficile* isolates were recovered from faecal samples at by culture on modified Brazier’s cycloserine-cefoxitin-egg yolk agar (Laboratory M, Bury, United Kingdom (UK)) without egg yolk and supplemented with 5 mg/L lysozyme (CCEYL) for 48 hours at 37°C in an anaerobic atmosphere. *Clostridium difficile* isolates were identified by their characteristic smell and colony morphology, fluorescence under long-wave UV light and a latex agglutination test for *Clostridium difficile* somatic antigen (Oxoid Ltd, Basingstoke, UK).

PCR ribotyping was performed at UKARU as described previously [12]. Briefly, DNA was extracted from overnight cultures of *Clostridium difficile* using Chelex 100 resin (BioRad, Hemel Hempstead UK). The 16S-23S intergenic spacer regions were amplified using primers P3: 5'-CTG GGG TGA AGT CGT AAC AAG G-3' and P5: 5'-GCG CCC TTT GTA GCT TGA CC-3'. DNA fragments were concentrated before electrophoreses and resolved using 3% Metaphor agarose (Cambrex Bioscience, Rockland, United States (US)).
Cases of healthcare-associated Clostridium difficile infection
Comparative data for presumed HA-CDI cases (onset of symptoms < 48 hours after admission to a healthcare facility or with onset of symptoms in the community within 12 weeks following discharge from a healthcare facility) [10,11] occurring during the same period were obtained from the results of routine CDRN testing. C. difficile culture and ribotyping was performed at regional CDRN laboratories, with data collated by the CDRN Reference Laboratory in Leeds. In order to check the accuracy of the classification of routine CDRN cases as HA-CDI, demographic data were collected for all submitted samples in one region (Yorkshire and Humber).

Statistical methods
Univariate analyses were used to compare differences between categories using chi-squared test or Fisher’s exact test (where sample size was small, i.e. less than 5, or less than 10 if only one degree of freedom). Median ages were compared by Mann–Whitney test. Ribotype diversity within groups was assessed using Simpson’s index, with 95% confidence intervals (CIs) demonstrating variance within groups. Univariate analyses were performed using SPSS version 19, and diversity analyses using PAST version 3.

Results
A total of 113 laboratories across England, all serving both hospitals and the community, referred 703 C. difficile toxin-positive (and C. difficile culture-positive) faecal samples from individual CA-CDI cases between March 2011 and March 2013 (i.e. median of six samples per laboratory, range: 1–25). The collected samples were approximately equally distributed over the two-year period. A dataset of 11,479 CDRN records, for the same period, were used as presumed HA-CDI cases for comparison with CA-CDI cases. CA-CDI cases were predominantly female, elderly (≥ 65 years of age) and resident in their own home (Table).

The most frequently identified ribotype causing CA-CDI was RT002 (95/703; 13.5%) (Figure 1).

CA-CDI cases were significantly more likely than HA-CDIs to be due to ribotype 002 (p < 0.0001). Although not as commonly isolated, ribotypes 020 and RT056 were also significantly more likely to be found in CA-CDI cases than in HA-CDI cases (p = 0.009 and 0.0001 respectively). Ribotypes known to be associated with enhanced pathogen virulence and poor clinical outcome (078 and 027) were fourth and eighth most frequently identified ribotypes in CA-CDI cases, respectively. Notably, ribotype 027 was found significantly more often in HA-CDI cases than in CA-CDI cases (p = 0.01). With the exceptions noted above, comparison of ribotypes causing CA- and HA-CDI showed a very similar ranking and prevalence distribution (Figure 1).

Cases referred to the national CDRN service (additional surveillance in conjunction with mandatorily reported CDI cases) were presumed to represent HA-CDIs. As these could conceivably contain CA-CDIs, however (for example, examined as part of outbreak investigations), we sought to compare the ribotype prevalences for CDRN-referred cases from one region in England (Yorkshire and Humber), comprising 14 distinct hospitals, with known low-level community-based testing, with those for the remainder of the CDRN-referred cases in England during the same study period. All ribotype frequency pairs were within plus or minus 1.9% of each other, with the exception of ribotype 027 (6.6% (708/10,754) CDRN England, 17.8% (265/1,489) CDRN Y and H); this discrepancy was due to hospital-based outbreaks of 027 in the Y and H region.

Age of cases
Three quarters of the CA-CDI cases (519/693) were aged ≥ 65 years. Frequencies of the most prevalent ribotypes (top 15) found in the study are shown with respect to patient age in Figure 2.

The prevalence of ribotype 078 in cases of CA-CDI was significantly higher in elderly patients (3.4% (6/174) vs. 8.7% (45/519) in those aged < 65 vs. ≥ 65 years, respectively; p = 0.019). Similarly, ribotype 027 prevalence increased from 2.9% (5/174) to 4.4% (23/519) in elderly patients with CA-CDI, rising further to 5.6% (15/269) in those over 80 years of age, although this trend was not statistically significant. Proportions of cases with CA-CDI with ribotype 002 were found to increase with age, but again this was not statistically significant.
Conversely, although numbers were small, proportions of ribotypes 050, 018, and 017 were relatively larger in patients younger than 65 years than in patients 65 years and older (4.0% (7/174), 2.9% (5/174), and 4.0% (7/174) vs. 1.7% (9/519), 1.7% (9/519), and 0.6% (3/519)) respectively. However, none of these were statistically significant (Figure 2).

Median ages of cases with a particular ribotype were generally comparable for CA- and HA-CDI patients. Notably, although numbers were small, cases with CA-CDI due to ribotype 017 infection tended to be younger than corresponding HA-CDI patients (56.5 years and 75 years, respectively; \( p = 0.13 \)).

Diversity of ribotypes decreased with increasing age in HA-CDI patients, while CA-CDI patients showed no such trend (Figure 3).

**Place of residence**

A fifth of the CA-CDI cases (125/525) in the study were associated with community-based residential care. Frequencies of the most prevalent ribotypes (top 15) found in the study with respect to patient residency and recent hospital admission are shown in Figure 4.

Patients with CA-CDI who were living in their own home and had no demonstrable hospital admission within the previous 12 months were classified as having no institutional or healthcare contact. Patients not residing in...
Figure 4

Top 15 *Clostridium difficile* PCR ribotypes from cases of community-associated *C. difficile* infection by place of residence (community-based residential care) (n = 125) or their own home (n = 525), or their own home and no hospital admission with the previous 12 months (n = 312), England, March 2011–March 2013.

Proportions of CA-CDIs caused by ribotypes 078, 020, 023 and 027 in patients with hospital admission within the previous three to six months were higher than in those with no evidence of hospital admission within the previous year, although these differences were only significant for ribotype 078 (12.0% (19/158) vs 4.5% (18/396); p = 0.005). Frequencies of several ribotypes, notably 002, 015 and 005, were found to be higher among patients who had no evidence of hospital admission within the previous year as compared with those admitted in the previous three to six months; only the difference in proportions of ribotype 005 was significant (9.8% (39/396) vs 2.5% (4/158); p = 0.003). Ribotype diversity was similar for CA-CDI cases with no evidence of hospital stay within the previous year compared with those admitted in the previous three to six months (Table, Figure 3).

History of antibiotic use

History of antibiotic use was the most poorly completed part of the CA-CDI case questionnaires (47.5% (334/703) completed). For those with available antibiotic history data, CA-CDI cases were significantly more likely not to have received any antibiotics in the four weeks before their CDI episode when compared with HA-CDI cases (CDRN data) (38.6% (129/334) vs 20.3% (1,226/6,028); p < 0.0001).

The three most common antibiotics/classes associated with CA-CDI cases were amoxicillin/clavulanic acid (16%; n = 61), amoxicillin/ampicillin (13%; n = 52) and cephalosporins (6%; n = 23); 4% (n = 14) had received a fluoroquinolone. Notably, these data do not take into account the relevant frequencies of antibiotic prescribing.

Frequencies of the most prevalent ribotypes (top 15) found in the study with respect to recent antibiotic use are shown in Figure 6.

A significantly higher proportion of ribotype 050 was associated with antibiotic use (0.78% (1/129) vs 5.8% (12/205); p = 0.013). For all other comparisons, p was greater than 0.05.

Patients with no institutional or healthcare contact and who did not receive any antibiotics in the previous four weeks, were classified as having no established risk factors for CDI. The prevalence of ribotype 002 was higher in those patients with no established risk factors when compared with those with at least one known risk factor, although this was not statistically significant (14.5% (9/62) vs 12.5% (52/415); p = 0.662).

Discussion

To the best of our knowledge, this is the first large study in the UK to compare the epidemiology of CA- vs HA-CDI. In marked contrast to earlier reports, when HA-CDI was closely associated with a small range of epidemic ribotypes [1,13,14], we found very similar ribotype diversity indices for CA- and HA-CDI.
of new, distinct *Clostridium difficile* genotypes causing infections was constant, suggesting the existence of a large reservoir(s) of *C. difficile*. If correct, this would tend towards a similar distribution of ribotypes causing HA- and CA-CDI, (as found in this study) assuming that there are no powerful selection pressures or niches for particular ribotypes that could promote CDIs in one setting versus the other.

In England, a pragmatic definition has been used in national surveillance to apportion CDI cases between hospitals (symptom onset after 72 hours following admission) and the community (symptom onset in the community or within the first 72 hours following admission to hospital) [8]. However, this definition may exaggerate numbers of cases with apparent CA-CDI as it fails to take into account recent previous hospital admission. Multiple, often large outbreaks were typical around the peak incidence of CDIs in the UK in 2007–08; since then there has been a ca 70–80% decrease in case frequency [13,14] This followed intensive public health campaigns that included multiple infection prevention and control measures designed to reduce transmission of *C. difficile* and alter prescribing of antimicrobials [16]. One of the most striking aspects of this control programme was the substantial decrease in prevalence of ribotype 027 CDIs. In 2007–08, this ribotype caused more than 50% of CDIs in England referred to the CDRN; in subsequent 12-month periods the corresponding proportions were 36% (in 2008–09), 22% (in 2009–10), 13% (in 2010–11), and 9% (in 2011–12) [13]. The control of this epidemic strain, which is associated with poor clinical outcome [17,18], has been paralleled by an increased heterogeneity of ribotypes causing CDIs [13]. This observation is also consistent with the similar distributions of strains found to be causing CA-CDIs and HA-CDIs in this study. Earlier studies in Sweden (1998 and 2004) also reported similar distributions of ribotypes among nosocomial and community settings [19,20]. Such data likely reflect the close interplay between hospital and community settings at times of relatively low levels of hospital-based CDI case-to-case transmission.

While *C. difficile* ribotype distributions were similar among cases of CA- and HA-CDI in our study, there were some notable differences. CA-CDI cases were significantly more likely than HA-CDI cases to be due to ribotype 002 and (less commonly) to ribotypes 020 and 056. Conversely, ribotype 027 was found significantly more often in HA-CDI cases than CA-CDI cases. Ribotype 002 is a relatively frequent cause of HA-CDI and is among several other long-recognised ribotypes, including 015, 014, 020 and 078, which have become more common in the UK, concurrent with the demise of epidemic ribotypes such as 027, 106 and 001 [9,13].

Studies have repeatedly demonstrated a lower median age in patients with CA-CDI compared with HA-CDI [19–22]. However, we did not find a statistically significant difference. Age-related differences may be confounded...
by ascertainment bias, including testing policy in hospital versus community settings. We speculate also that differences between studies with respect to age may be driven by ribotype distribution in population cohorts. Data from our study showed that infections associated with certain ribotypes (002, 027, 078) were more common in patients aged ≥ 65 years. Notably, CA-CDIs due to ribotype 078 were ca 2.5-fold more likely to affect an individual aged ≥ 65 years. Median ages of CA-CDI cases and HA-CDI cases were very similar for infections due to ribotypes 002, 027 and 078. A Dutch study in 2008 found a significant difference in the median age of CDI cases due to ribotypes 078 and 027 (67.4 vs 73.5 years, respectively) [21]. In our study, although median age was lower for cases due to ribotype 078 (80 years), vs 82 years for ribotype 027, this difference was not statistically significant. Although numbers were small, ribotype 017-associated CA-CDIs were more than three times more likely to affect a younger individual. Additionally, the median age of patients with ribotype 017-associated CDI was significantly lower in CA-CDI patients than in corresponding HA-CDI patients, suggesting that a true association may exist between ribotype 017 infections and the younger patient in a

CA: community-associated; CDI: Clostridium difficile infection; CI: confidence interval; HA: hospital-associated; NA: not available.

a HA-CDI data were obtained from the Clostridium difficile Ribotyping Network (CDRN).

b Simpson’s index was calculated where a ribotype result was available.
community setting. We also found that ribotype diversity decreased with increasing age in HA-CDI patients, while CA-CDI patients showed no such trend.

Recent US studies (2013–15) found that about a third of CDI cases were CA-CDIs [3,4,23]. However, the increasing use of nucleic acid amplification tests (NAATs) alone for the diagnosis of CDI may be confounding US data, given the clear potential for large overestimates of CDI incidence by this sensitive but poorly specific diagnostic approach [24]. Indeed, use of NAATs was found to significantly correlate with higher reported CA-CDI incidence [3]. By contrast, at the time of our study, 79% and 94% of UK hospitals in 2011–12 and 2012–13, respectively, were using an optimised method (screening test followed by a toxin test) for CDI diagnosis [24]. In the US, between 2009 and 2011, ca 40% of cases defined as CA-CDI had high-level exposure to healthcare (i.e. surgery, dialysis, emergency or urgent care visit, inpatient care with no overnight stay, or healthcare personnel with direct patient care), despite no hospital admission in the previous 12 weeks [4]. A further ca 40% had low-level healthcare exposure (i.e. an outpatient visit with a physician or dentist). Thus, only ca 20% of CA-CDI cases had no recorded healthcare contact in the previous 12 weeks. Of note, HA-CDI was taken to include cases occurring in nursing homes (and acute care hospitals or long-term acute care hospitals). There is a key issue regarding consistency between studies and healthcare systems concerning definitions of ‘nursing homes’. In the US, there are more than 15,000 nursing homes, each averaging over 100 licensed beds [25]. By contrast, care homes in England (about 17,500) with nursing capability (n = ca 4,000) are about half the size of their US counterparts; typically both nursing and residential care are provided within the same facility [26-28]. In England, about 4% (ca 375,000) of the population aged over 65 years live in care/nursing homes, rising to almost 20% of those aged ≥ 85 years. Thus, a sizeable minority of elderly people live in care homes, but determining whether individuals are receiving nursing as opposed to residential care is problematic, given that care needs may fluctuate. Subjects receiving residential care are not receiving healthcare per se, but instead are helped with normal daily living activities. This highlights the dilemma of how best to categorise subpopulations resident in care homes.

A limitation of our study is that we did not ascertain the level of nursing received by CA-CDI cases in care homes. We chose to define CA-CDI cases to include non-hospital-associated cases living in care homes, noting that the great majority of residents in such settings are not receiving nursing care [26-28]. However, by examining subpopulations resident in the community in care homes, we did demonstrate a clear predominance of epidemic ribotypes, notably 027 and 001, in patients with institutional contact compared with those living in their own home. High prevalence of ribotype 027 CDIs in nursing home residents has been reported in Germany in 2012 [29], but data in this setting are limited [30]. Carriage of C. difficile, CDI and subsequent transmission of the pathogen are more common in elderly patients [1], and so it is not surprising that (older) patients associated with community-based residential care had a different distribution of ribotypes compared with community residents living in their own home. Furthermore, we found that CDI cases either resident in their own home or with no evidence of hospital stay within the previous 12 months were associated with higher relative diversity indices than either those residing in care homes or admitted to hospital within the previous six months. More simply, patients with less recent contact with hospitals were more likely to be affected by a more diverse range of C. difficile strains than those with more recent contact, presumably reflecting a lower risk of contact with epidemic strains. We did not collect information on CDI outbreaks as this was beyond the scope of the study.

While antibiotic exposure is a key risk factor for CDI [1,31-33], our study has again demonstrated that over a third of CA-CDI cases were associated with no recent history of a prescribed antibiotic, as seen in other studies [22,34-37]. Indeed, we found that CA-CDI cases were nearly twice as likely to have had no antibiotics preceding infection than HA-CDI cases (p<0.0001). Certain ribotypes notably 001, 002 and 015 were more commonly associated with patients receiving no antibiotics before their infection. Such data indicate that antibiotic history might be less of a prerequisite for infection with these C. difficile ribotypes and alternative factors support the spread of these ribotypes in the community setting. Other risk factors associated with CA-CDI have been extensively reported, including gastric acid suppressants and contact with infants under two years-old [34,38]. However, no data currently exist to associate such factors with CDI due to ribotypes 002 and 015 in the community setting.

There is increasing evidence linking CDI to environmental sources including water and food [39-41]. Although these studies have identified clinically relevant ribotypes, notably including 078, in foodstuffs, food-borne transmission of C. difficile has not been demonstrated. For example, we recently found no differences between hospital and community onset of infection, or in food or environmental exposures between ribotype 078 CDI cases and those caused by other ribotypes [42]. However, conditional logistic regression modelling adjusting for age found that ribotype 078 CDI cases were markedly more likely than other cases to report prior antibiotic exposure (odds ratio: 5.1 (95% CI: 1.6-16.3); p = 0.002) [42]. More studies employing WGS are needed to understand the significance of community C. difficile reservoirs to human disease. This is probably best achieved early as new strains emerge, not least because once established it becomes more difficult to untangle true risk factors from confounding issues. The emergence of ribotype 244 in Australasia is a good example of the use of WGS to map the spread
of this new clone primarily causing CA-CDI, although a proven community reservoir remains elusive [43].

In summary, while there were examples of ribotypes that significantly predominated in CA- or HA-CDIs, we found very similar ribotype diversity indices, ranking and relative strain prevalences in these two groups. Ribotype 002 was associated with CA-CDI, and there was a clear predominance of epidemic ribotypes, notably 027 and 001, in patients associated with community-based residential care compared with those living in their own home. CA-CDI cases were nearly twice as likely to have had no antibiotics preceding infection than corresponding HA-CDI cases during the same period. Our nationally sourced data emphasise the close interplay between hospital and community settings, particularly when there are relatively low levels of hospital-based case-to-case transmission of C. difficile and thus less dominance of epidemic C. difficile clones.
