We report the preliminary findings of the investigation of an outbreak of foodborne *Salmonella* Bareilly. Between August and November 2010, there were 231 laboratory-confirmed reports of *S.* Bareilly in the United Kingdom. A case–control study showed that consumption of bean sprouts was significantly associated with illness. The investigation concluded that raising public awareness to ensure the correct preparation of raw bean sprouts during cooking was the principal means of preventing further cases.

**Background**

Consumption of bean sprouts has previously been associated with outbreaks of *Salmonella* infection [1,2]. There was previously an outbreak of *S.* Saint-Paul infection associated with bean sprouts in the United Kingdom (UK) in 1988 [3].

*Salmonella enterica* subsp. *enterica* serovar Bareilly, or *S.* Bareilly, is a group C1 serovar first identified in India in 1928 [4]. In years when no outbreaks occur, on average 30 to 50 cases are reported in England and two to five cases in Scotland.

The current investigation began on 27 August 2010, when an outbreak of *S.* Bareilly was reported following a wedding reception in Greater Manchester in northwest England. An increase in the number of detected cases of *S.* Bareilly was also reported in Scotland on 2 September 2010 and more widely in England on 10 September 2010. The outbreak was first reported to the European Centre for Disease Prevention and Control (ECDC) Epidemic Intelligence Information System (EPIS) site on 14 September, providing an image of the outbreak pulsed-field gel electrophoresis (PFGE) profile. Between 14 September and 1 October, 10 EPIS members responded with no indication of co-temporal increases in findings of this serovar. One country (Ireland) reported the same profile in a case who had visited London in September, but no further exposure data was available.

Preliminary information from cases in Scotland, from the wedding outbreak investigation, and from trawling questionnaires including questions on a comprehensive range of possible risk factors including foodstuffs, raised the hypothesis of salad leaves and/or bean sprouts as possible vehicles of infection. A matched case–control study including 34 cases meeting the case definition was conducted across the UK beginning on 21 September 2010. At the time the case–control study started there were some 40 cases who had not done the trawling questionnaire and who were not linked to the wedding outbreak.

Between the beginning of August and the 19 November 2010, there were 231 laboratory-confirmed reports of *S.* Bareilly across the UK. 10 of these were linked to the wedding in Greater Manchester.

**Case–control study**

**Definition of cases and controls**

The case–control study was conducted using telephone interviews with cases of *S.* Bareilly fitting the confirmed case definition and with controls selected by sequential digit dialling based on the telephone number of the case, to match on broad geographical location of residence.

Confirmed cases were defined as persons aged 18 and over with microbiologically confirmed infection with *S.* Bareilly with a sample received at the Health Protection Agency (HPA) *Salmonella* Reference Unit or the Scottish *Salmonella, Shigella* and *Clostridium difficile* Reference Laboratory on or after 1 August 2010 with (i) no history of foreign travel or close contact with a case of diarrhoea in the seven days prior to the onset of illness, (ii) who did not attend the wedding in the
Results of case–control study

Data on 34 cases (response rate of 77%) meeting the case definition, with onset dates ranging from 13 September 2010 to 14 October 2010, and 64 eligible controls were collected. Cases had a mean age of 49 years (standard deviation 15.1 years) and 21 of 33 cases were female. A total of 32 of 34 reported diarrhoea and seven of 34 reported vomiting. Five cases had been hospitalised as a result of their infection. Cases reported a median duration of illness of 7.5 days (range 2 to 30 days).

In univariate analysis, consumption of bean sprouts, consumption of any salad leaves and age younger than 65 years were all significantly associated with illness. In the final conditional logistic regression model, only consumption of bean sprouts was significantly associated with illness (crude matched odds ratio (OR) 8.3, 95% confidence interval (CI)1.8 to 38.7; adjusted matched OR 6.8, 95% CI 1.4 to 33.0). Of the 15 cases who recalled consumption of bean sprouts, six had eaten them in the home (four had purchased them from supermarkets). 10 had eaten them in take away meals or at restaurants. (One person had eaten them from both sources.)

In total, 94 of the 231 patient isolates underwent further typing and 87 of these were found to be of PFGE type SBARXB.0016.

Food investigation

The complex distribution network of bean sprouts and the results of routine microbiological testing of bean sprouts by suppliers for quality control purposes in the UK were also investigated. In August and September 2010, two UK suppliers identified in the investigation of the Scottish cases (suppliers A and B) had recorded the identification of a group C Salmonella in samples of bean sprouts which were intended to be cooked by consumers. None of these isolates were available for further characterisation. Routine regular testing of samples at an upstream supplier (supplier C, who supplies B, who in turn supplies A) had been consistently negative for many years.

Samples of bean sprouts from suppliers B and C were collected. S. Bareilly of a PFGE type indistinguishable from the outbreak cases was identified in a packet of bean sprouts produced by supplier C. Supplier C received mung bean seeds from upstream suppliers who sourced mung bean seeds from China or Myanmar. The investigation is ongoing.

Discussion

Our epidemiological and microbiological investigations implicated bean sprouts as a vehicle for S. Bareilly transmission, consistent with previous research showing that bean sprouts can be a vehicle for Salmonella transmission [1].

Case–control study designs are prone to a number of biases, the most important being recall bias. Although...
there was a small amount of press interest in the possible link between Salmonella and bean sprouts. In our study, controls were selected by random digit dialling, which may result in a low response rate and controls that are not representative of the general population. This is however unlikely to account for the strong observed association in our study.

Bean sprouts follow a complex path from farm to table that includes growing, harvesting, processing and shipping of mung bean seeds, followed by sprouting (normally at temperatures of 20-30 °C with high humidity) and distribution of the finished product. Seeds may arrive already contaminated or contamination may occur at any point of production and distribution. As in previous outbreaks, this investigation concluded that the seeds were likely to have been contaminated, as investigations at suppliers found little potential for cross contamination of sprouted seeds [7]. Based on the experience of this investigation, the methodology used for routine microbiological quality control testing of bean sprouts may not be sensitive to low levels of Salmonella contamination. This may have implications for future testing protocols.

The bean sprouts implicated in this investigation were not ready to eat products and would be safe to eat if the instructions for correct preparation (washing and cooking until piping hot) were followed. Public health interventions resulting from this investigation focussed on communications to the public and to public and environmental health professionals advising of the correct preparation of bean sprouts, and on improving food labelling where this was ambiguous. Given that Salmonella Bareilly was only detected in raw mung bean sprouts intended to be cooked, rather than ready to eat bean sprouts, and the producers and suppliers have not been found to be at fault in our investigations, no product recalls were deemed necessary. No other interventions besides addressing the issue of potentially misleading labels were put in place with suppliers and producers. At the time of writing, the numbers of reports of Salmonella Bareilly infection in the UK had fallen back to near expected levels.
