Tuberculosis (TB) surveillance commonly focuses on pulmonary (PTB) where the main organ affected is the lung. This might lead to underestimate extrapulmonary TB (EPTB) forms, where in addition to the lung other sites are affected by TB. In Germany, TB notification data provide the main site and the secondary site of disease. To gain an overview of all the different EPTB forms, we analysed German TB notification data between 2002 and 2009 using information on both main and secondary disease site to describe all individual EPTB forms. Further, we assessed factors associated with meningitis using multivariable logistic regression. Solely analysing the main site of disease, lead to one third of EPTB manifestations being overlooked. Case characteristics varied substantially across individual extrapulmonary forms. Of 46,349 TB patients, 422 (0.9%) had meningitis as main or secondary site. Of those, 105 (25%) of the 415 with available information had died. Multivariable analysis showed that meningitis was more likely in children younger than five years and between five and nine years-old (odds ratio (OR): 4.90; 95% confidence interval (CI): 3.40–7.07 and OR: 2.65; 95% CI: 1.40–5.00), in females (OR: 1.42; 95% CI: 1.17–1.73), and in those born in the World Health Organization (WHO) regions of south-east Asia (OR: 2.38; 95% CI: 1.66–3.43) and eastern Mediterranean (OR: 1.51; 95% CI: 1.02–2.23). Overall, EPTB manifestations, including meningitis, which is often fatal, were underestimated by routine analysis. We thus recommend using all information on disease manifestation generated by surveillance to monitor severe forms and to transfer the gained knowledge to TB case management where awareness of EPTB is most important.

Introduction

Global tuberculosis (TB) control focuses on pulmonary tuberculosis (PTB) to prevent transmission and reduce the number of new cases. Thus, in surveillance, TB cases are classified as pulmonary TB whenever lungs are involved, irrespective of any additional involvement of other organs [1]. However, extrapulmonary TB (EPTB), a collective term for diverse manifestations affecting any other anatomic site than the lung parenchyma and the tracheobronchial tree, substantially contributes to the TB burden. In the European Union and European Economic Area (EU/EEA), 22% of TB patients notified in 2010 only had extrapulmonary manifestations [2]. EPTB is more common in immunocompromised individuals, especially people living with human immunodeficiency virus (HIV) [3-7], but also females and different ethnic groups [3,5-10]; for example, in the United Kingdom (UK) all non-white ethnic groups were associated with EPTB [8]. Socio-behavioural factors including smoking and alcohol abuse, in contrast, were associated with pulmonary manifestation [6,7,11-13].

Some EPTB forms, such as meningitis cause severe disease. Reported case fatality ranges from 20 to 69% [14] in different settings worldwide with up to half of surviving patients presenting with irreversible sequelae, including paraplegia, blindness, motor and cognitive deficits [15-19]. Prognosis is largely influenced by early diagnosis and adequate treatment [4,17-19].

Meningitis TB most commonly occurs in infants and toddlers, mainly within three months after infection [3,20]. Its development may be influenced by genetic factors, differing across ethnic groups and certain strains of Mycobacterium tuberculosis complex [7,21]. Further, vitamin D deficiencies [22] and underlying conditions influencing immunocompetency, including HIV infection [13,19,21,23] diabetes mellitus, malignancy and recent corticosteroid treatment, as well as alcohol abuse (in adults), have been described as risk factors for meningitis TB. Bacillus Calmette–Guérin (BCG) vaccines were reported to have a preventive effect in young children (30–82%) [24].
In 2010, Germany, a low incidence country for TB (5.3 cases per 100,000 population in 2010), reported that 21% of patients had exclusively EPTB [25]. National TB surveillance captures disease manifestations as main and secondary site of disease (whereby only up to two sites can be recorded) and classifies extrapulmonary forms into 11 sites as recommended by the World Health Organization (WHO): intrathoracic lymph nodes (LN), extrathoracic LN, pleura, genitourinary tract, abdomen, spine, bone and joints, meninges, other central nervous system (CNS), disseminated TB and any other organ [1]. Lungs, when affected by TB, can only be recorded as the main site of disease. If two different extrapulmonary sites are affected, physicians are asked to classify the more severely affected one as main site of disease. In line with other countries, surveillance data analyses and reporting focus on the main site of disease (privileging PTB). This may lead to underestimate EPTB manifestations overall, as well as EPTB forms causing severe disease such as meningitis TB.

We conducted a study to (i) estimate the frequency of all individual EPTB forms, irrespective of the classification as main or secondary site, (ii) describe demographic and clinical characteristics of patients affected by specific extrapulmonary sites of disease and (iii) identify factors associated with meningitis TB.

Methods

Data source

We used case-based TB surveillance data from Germany between 2002 and 2009, electronically reported to the Robert Koch Institute (RKI) until 1 August 2010, and population data from the Federal Statistical Office to calculate incidences [26]. Surveillance defines active TB cases based on clinical diagnosis and the indication of a full-course of anti-TB treatment regimen with or without bacteriological confirmation or known epidemiological link to another confirmed case [27]. The notification system, case definitions and diagnostic procedures have remained largely the same over the investigation period. This is as well reflected by the stable proportion of bacteriologically-confirmed cases (72% to 75%) from 2002 to 2009.

Data analysis

We grouped cases into three categories: PTB only, both PTB and EPTB, and EPTB only (Figure 1), and calculated mean annual incidences (cases/100,000 populations). Further, we compared the proportions of these three groups in 2002 to those in 2009.

We calculated the frequency of all 11 EPTB sites (i) using information regarding the main site of disease only and (ii) combining information from main and secondary sites of disease and compared the number of EPTB affected sites detected using either classifications. As up to two different disease sites per patient can be recorded, the same patient may belong to two different disease manifestation groups.

To identify characteristics of patients affected by specific extrapulmonary manifestations, we tabulated demographic (i.e. age, sex, country of birth (foreign vs. German)) and clinical information (i.e. hospitalisation, duration of hospitalisation (in days) and case fatality ratio (CFR)) by site of disease. We presented proportions for categorical variables and median and interquartile-ranges (IQRs) for continuous variables. We excluded implausible values (e.g. negative values) in the duration of hospitalisation from the analysis.

To identify factors associated with meningitis TB, we compared meningitis (both as main and as secondary site) with non-meningitis TB cases in terms of possible exposures using the chi-squared test, odds ratios (OR), 95% confidence intervals (CI) and two-sided p-values. Exposures examined included age, sex, country of birth, as well as being a new case, i.e. not previously treated. We grouped countries of birth into Germany,
Turkey, Newly Independent States of the former Soviet Union (NIS), other countries of the WHO European region, as well as other WHO regions. We considered four age groups (individuals younger than 5 years, 5 to 9 years, 10 to 14 years and 15 years or older). We included variables associated at p=0.2 in the univariate analysis in a multivariable logistic regression analysis using forward selection. We tested pairwise interactions of independent variables at each step and only included them when the likelihood ratio test pointed to an improvement of the model with a p-value less than 0.05.

We analysed data using Excel (version 11, Microsoft Corporation Redmond, Washington, USA) and Stata (version 12.1, StataCorp LP, TX, USA) software.

**Results**

**Study population**
From 2002 to 2009, a total of 46,730 TB patients were reported in Germany (mean annual incidence of 6.3 cases per 100,000 population). Of the 46,349 patients with information on the anatomic site of disease, 32,262 (70%) had exclusively PTB, 4,097 (8.8%) had both PTB and EPTB and 9,990 (22%) had EPTB only (Figure 1). The TB incidence decreased from 9.3 to 5.4 cases per 100,000 populations in the study period. However, the proportions of disease manifestations remained relatively stable: There was a 1.1% decrease in exclusively PTB, a 0.5% increase in both PTB and EPTB and a 0.6% increase in exclusively EPTB between 2002 and 2009.

**Characteristics of extrapulmonary tuberculosis patients**
Overall, EPTB patients were similar to PTB patients in terms of median age and CFR (Table 2). However, they were more frequently female (49% (6,956/14,072) vs...

NA: not applicable; TB: tuberculosis; WHO: World Health Organization.
36% (13,165/36,324)) and more often foreign-born (51% (6,998/13,650) vs 42% (14,609/35,039)).

Across the individual extrapulmonary forms there were large differences in case characteristics. Genitourinary TB patients, for instance, were characterised by a high median age (61 years, IQR: 46–72) and only 32% (496/1,542) of foreign-born.

The CFR was only 1% (45/4,076) in extrathoracic LN, but 27% (138/516) in disseminated TB. The median duration of hospitalisation was longest in meningitis and other CNS TB (36 days, IQR: 15–60 and 36 days, IQR: 19–52, respectively).

Meningitis tuberculosis

Meningitis TB was reported in 0.9% (422/46,349) of patients as main or secondary site, and in 0.6% (288/46,349) as the main site only. This manifestation was most frequent in children, affecting 3.9% (34/882) of those younger than five years old, 2.2% (10/460) of the five to nine year-olds, and 1.3% (5/388) of the 10 to 14 year-olds. Though, only 0.8% (373/44,612) patients aged 15 years and above had meningitis, this age group accounted for 88% (373/422) of all meningitis patients. These proportions were stable from 2002 to 2009 in all age groups. Meningitis was more frequent among female than among male patients (1.1% (207/18,408) and 0.8% (215/27,896), respectively).

The proportion of patients with meningitis varied by the region of origin, ranging from 0.5% (20/4,486) among patients born in the NIS, and 0.9% (227/25,051) among those born in Germany, to 2.0 % (35/1,787) among those born in the south-east Asia WHO region (Table 3).

In multivariable analysis, compared with non-meningitis TB cases, patients with meningitis TB were more likely to be children younger than 5 years (OR: 4.90; 95% CI: 3.40–7.07) and children between five and nine years-old (OR: 2.65; 95% CI: 1.40–5.00) (Table 3). Female patients were more affected than males (OR: 1.42; 95% CI: 1.17–1.73). Meningitis TB patients were less likely to be born in the NIS (OR: 0.54; 95% CI: 0.34–0.85) than in Germany. There were no significant differences for patients born in Turkey or in the Americas, the western Pacific, the remaining European and the African WHO regions. An origin of the south-east Asia and the eastern Mediterranean region was significantly associated with meningitis (OR: 2.38; 95% CI: 1.66–3.43; and OR: 1.51; 95% CI: 1.02–2.23, respectively).

Being a new case as well as the examined pairwise interaction terms was not statistically significant in the multivariable model, nor did they contribute to improve the model fit. They were therefore excluded from the final model.
The CFR of meningitis TB patients was 25% (105/415) overall, but higher in adults than in patients younger than 15 years (27% (98/366) vs. 14% (7/49); Figure 2). In children, meningitis accounted for about half (7/13) of all illness-related deaths.

Discussion

Our investigation of national TB surveillance data for EPTB between 2002 and 2009 indicated that in Germany analysing solely the main site of disease, as commonly done in surveillance, leads to overlooking one third of extrapulmonary manifestations reported as the secondary site. This applied to all individual EPTB manifestations including severe forms. European Centre for Disease Prevention and Control (ECDC) data indicate that, on average, about 6% of all TB patients in EU/EEA countries are reported with both PTB and EPTB [2]. This suggests that there could be similar increases in proportions of extrapulmonary forms, such as meningitis, in other countries if both main and secondary site of diseases were considered.

Patients with any extrapulmonary manifestations were more often female and born abroad. This supports earlier findings [5,6,8,10,28,29] and may reflect differences in TB pathogenesis related to sex [30] and ethnicity [8], as well as risk factor patterns varying by sex and region of origin [6-8,10]. Exceptions, such as the high proportion of genitourinary TB patients being born in Germany, are partly explained by the advanced patients’ age, in which the proportion of foreign-born individuals is small in Germany [31]. Such interactions across case characteristics underline the need for stratified and multivariable analyses, as we illustrated for meningitis TB.

Overall 0.9% TB patients had meningitis, whereas only 0.6% had been reported as main site of disease. Hence, re-classification increased the number of reported cases by a factor of 1.5. A similar proportion (0.5%) of meningitis TB was found in Germany from 1996 to 2000, based on main site of disease only [28]. This stable proportion over time, in a context of a decrease in overall TB case numbers, suggests that there was neither a rise nor a particular progress in reducing this severe form.

Children younger than five years were most affected by meningitis; representing 8% of all meningitis cases, though accounting for less than 2% of TB patients in Germany. This is in line with a 1970 to 2000 cohort study of CNS TB patients in Canada, reporting that 10% of CNS cases were younger than five years of age [32].

While meningitis was rare (0.8%) among TB patients who were 15 years and older, this age group accounted for 88% of all meningitis patients. A similar age distribution of meningitis cases was observed in a cohort study in Canada, whereby the age group older than 15 years contributed to 82% of all meningitis patients [32]. A similar value of 76% was found for this age group in a retrospective analysis of notified meningitis cases in Denmark [19]. These countries have age structures comparable to Germany. Meningitis TB cases in adults may be an expression of age-specific risk factors including diabetes mellitus and immune compromising conditions [19,21].

In multivariable analysis, meningitis TB remained independently associated with young age and being female, similar to findings from Canada [32], as well as specific regions of origin. The association of meningitis with south-east Asia and eastern Mediterranean regions of origin is consistent with high proportions of all EPTB in patients born in these regions, and a low proportion in patients born in the NIS (data not shown). As to meningitis in particular, differences by region of origin might be shaped by the regions’ HIV prevalence, which is relatively high in the south-east Asia region [33], and different levels of BCG vaccination and different BCG strains in use. BCG has been withdrawn based on risk-benefit assessments from the immunisation schedule since 1998 in Germany, in line with other low incidence countries [34,35], but remains endorsed and widely used elsewhere [36]. These findings need to be interpreted with care given that meningitis case numbers were small for some regions of origin, and that risk factor patterns may differ across countries within one WHO region.

Meningitis was a severe EPTB form in terms of longest median hospital stay and case fatality. One quarter of patients with meningitis died and the CFR was almost twice as high in adults as in children. Similarly, a long term mortality study on meningitis TB patients in Denmark, from 1972 to 2008, reported that patients aged between 16 and 60 years had a 2.68 times increased risk of death compared to children [14]. The observed 14% CFR in children is higher than those described by hospital-based studies in Spain (11%; N=28) and Argentina (7%; N=40) [17,18]. However, case inclusion criteria in those studies might have differed from surveillance data and case numbers were small.

Our investigation was solely based on national routine TB surveillance data consisting of a legally defined variable set.

The data source did not contain information on comorbidities associated with EPTB such as HIV/ acquired immunodeficiency syndrome (AIDS) or diabetes mellitus, on BCG vaccination status, on socio-behavioral factors including smoking and alcohol consumption, or treatment, precluding comprehensive risk factor analyses for EPTB forms.

Our study was subject to several limitations. First, data on hospitalisation were not complete as they do not belong to the surveillance key variables demanded and validated with high priority. A reporting bias, for instance, if longer hospitalisations were more frequently known and documented, may exist. Second,
miscategorization between meningitis and other CNS TB or differences in case ascertainment among physicians cannot be entirely ruled out. For this reason, we ran the multivariable analysis twice, first only with meningitis TB (as presented), and second merging meningitis with non-meningitis CNS TB cases as the outcome of interest. The findings of both models did not vary markedly. Only the association with the WHO African region had additionally become significant.

Conclusion

National TB surveillance data provide both, information on occurrence of disease and its severity in terms of CFR and hospital stay. This information is needed to refine estimates of the Mycobacterium tuberculosis complex-related disease burden, currently restricted to pulmonary or pooled TB data [37], and to prioritise across different pathogen-related diseases within a country [38]. Site-specific analyses of EPTB forms, as shown for meningitis, help to target future research on risk factors, clinical outcome, diagnostic tools, and preventive and therapeutic options adapted to the individual manifestations.

As to TB case management, knowledge of population groups most affected by extrapulmonary sites helps physicians to timely consider EPTB as differential diagnosis. This is important in low incidence countries with small patient numbers and risk of waning expertise. Given the frequent co-occurrence of pulmonary and extrapulmonary sites, routine screening for PTB among EPTB patients, and vice versa, is essential.

Averting meningitis and other severe TB forms through timely contact tracing and preventive chemotherapy, in agreement with national recommendations [39], needs to be of high priority.

Altogether, EPTB manifestations, including often fatal meningitis, are more widespread in Germany than so far reflected by routine analyses. We thus recommend to monitor severe disease more closely using all information on disease manifestation and severity generated by surveillance, and to transfer the gained knowledge to TB case management where awareness of EPTB is most important.

Acknowledgements

We would like to thank all notifying physicians, laboratories, local and state health departments contributing to the TB surveillance in Germany. We further thank Yvan Hutin for valuable comments on the manuscript.
