Zika virus (ZIKV) has been on the agenda of virologists since many years already. Laboratories dealing with imported tropical diseases consider ZIKV infection among the differential diagnoses in cases of fever after travel to tropical Africa and Asia. The confirmation of autochthonous cases of this Old World flavivirus infection in Brazil in May 2015 was however surprising [1]. Already one month later, in June 2015, a rapid communication in Eurosurveillance provided a hint towards the unrecognised dimension of the outbreak. The relatively inconspicuous disease had already made it to Europe by March 2015, in the blood of an Italian traveller returning from Brazil [2]. One of the possible reasons for the ‘arbovirus community’ to stay somewhat inert about the outbreak initially was the introduction of chikungunya virus to Central and South America about one year earlier [3]. It seemed that ZIKV was just another example of an Aedes-transmitted and primate-associated arbovirus that had made it into the virgin soil environment of the neotropics, and moreover a harmless one from a clinical perspective.

A new dimension to the emergence of ZIKV was added in October 2015, when the Brazilian Ministry of Health (MoH) expressed concern about an increased incidence of microcephaly in newborns in the north-eastern part of the country [4]. These cases followed the assumed arrival and spread of ZIKV with a delay that made congenital infection plausible. Microcephaly had never been reported in connection with ZIKV infection before – but admittedly had not been assessed in any systematic way during previous outbreaks. In this issue of Eurosurveillance, Besnard et al. present a summary of 19 cases with a wide range of congenital cerebral abnormalities with and without microcephaly [5]. In all of these cases, the times of gestation most vulnerable for neurological fetopathies fell into the height of the 2013 to 2014 ZIKV outbreak in French Polynesia.

There is a whole number of viruses causing congenital neural malformations in humans. Cytomegalovirus, parvovirus B19 and varicella zoster virus are of highest concern in Europe. Rubella virus, the most relevant example historically, is today very rare as a cause of embryo- and fetopathy in Europe thanks to comprehensive vaccination programmes.

The threat of cerebral malformations in connection with ZIKV is difficult to express in numbers. The emotional component not only for expecting mothers and the possibility to miss a window of opportunity for study and intervention have already triggered ad hoc funding programmes and pragmatic approaches to extract information from available data [6]. It is not in spite of the emotional component, but because of it, that we should look at the problem from a rational perspective.

Most viral infections that cause fetopathy have a low manifestation index. Almost certainly, also the ZIKV will cause harm in only a small proportion of fetuses in the many pregnant women recently and currently exposed to the virus. Based mainly on data from the outbreak in French Polynesia, a recent study projected that women infected by ZIKV during the first trimester of pregnancy may have a risk of fetal microcephaly of 1% [6].

In the presently affected regions, where people are similarly exposed and immunologically naïve towards ZIKV infection, high rates of unnoticed infection are to be expected - including in pregnant women. The 6,158 suspected cases of microcephaly reported in Brazil by 9 March 2016, are likely to represent only a small fraction of the many pregnant women who got infected during 2015 [7].

Another issue is the reporting bias and classification of microcephaly. In autumn 2015, the Brazilian MoH strengthened and emphasised microcephaly surveillance, whereas notifications before this time occurred on a more routine basis. The media coverage of the ZIKV infection /microcephaly connection contributed an additional stimulus for reporting. A preliminary research manuscript by Rocha et al. suggests that the
The increase of microcephaly may represent a complex effect on the local population that could include other factors such as unrecognised or underdiagnosed pathogens. These factors may promote microcephaly alone or in concert with ZIKV infection. The Bulletin of the World Health Organization (WHO) Zika Open [10] carries a research manuscript that follows the incidence of microcephaly from 2012 to 2015 in Paraiba, Brazil. The literature now contains several reports on cases with microcephaly and ZIKV detection in amniotic fluid, blood, and even central nervous tissue of fetuses with signs of microcephaly. The paper by Besnard et al. includes eight cases of microcephaly [5]. Of the five cases that were tested virologically, four yielded ZIKV by RT-PCR and maternal history was positive for symptoms compatible with ZIKV infection during pregnancy. With every new case report published, we perceive the link between ZIKV infection and microcephaly to become stronger. There is probably truth to this. However, we should remember that case reports do not establish a causative link between the virus and microcephaly. As always at the beginning of epidemiics, studies tend to focus on cases but not controls. What fraction of healthy pregnancies might reveal evidence for ZIKV infection if sampled at the peak of an outbreak, assuming attack rates of 10% or even higher in the adult population? At the time of writing, 583 cases of microcephaly in Brazil have been completely investigated including objective neurological criteria and virological laboratory tests. Only 67 (11.5%) were confirmed positive by laboratory tests [7].

A recent correlative analysis noted 2.8 cases of microcephaly per 10,000 births in federal states of Brazil with obvious ZIKV circulation, vs 0.6 cases per 10,000 in states without laboratory evidence for the virus [9]. These numbers suggest a 4.7-fold increase in ZIKV-affected regions overall. In the two most affected states in the north-east, the rate was increased up to ca 18 and 24-fold, respectively. This local concentration is remarkable. According to the latest epidemiological update by the Pan American Health Organization (PAHO), 80% of suspected cases and 97% of confirmed cases in Brazil are reported from the north-east region still. Will the incidence in other ZIKV-affected states in the north-east rise?

The increase of microcephaly may represent a complex effect on the local population that could include other factors such as unrecognised or underdiagnosed pathogens. These factors may promote microcephaly alone or in concert with ZIKV virus infection. The Bulletin of the World Health Organization (WHO) Zika Open [10] carries a research manuscript that follows the incidence of microcephaly from 2012 to 2015 in Paraiba, Brazil.
