We report the longitudinal follow-up of Zika virus (ZIKV) RNA in semen of a traveller who developed ZIKV disease after return to the Netherlands from Barbados, March 2016. Persistence of ZIKV RNA in blood, urine, saliva and semen was followed until the loads reached undetectable levels. RNA levels were higher in semen than in other sample types and declined to undetectable level at day 62 post onset of symptoms.

Case report
In March 2016, a previously healthy man in his 50s, reported to the travel clinic at Erasmus MC, with arthralgia, conjunctivitis, fever (≥ 38.1°C) and rash. The patient had returned eight days earlier from a four day business trip to Barbados. He had been vaccinated according to the Dutch guidelines for travellers, including for yellow fever (vaccinated in 2012). He remembered being bitten by mosquitoes during early mornings on the island. Four days after returning to the Netherlands he suffered from staggered joint pain in ankles, elbows and hand joints. Two days after the start of the joint pain he developed fever up to 38.5°C, a total body macular rash, followed by conjunctivitis. The fever disappeared after three days as well as the joint pain, rash and conjunctivitis. No haematospermia was reported. The patient recovered completely. At the time of his visit in Barbados both ZIKV and chikungunya virus (CHIKV) were circulating on the island.

Laboratory observations
Upon first presentation at the clinic, plasma and urine were collected. CHIKV RNA was not detectable by real-time reverse-transcription polymerase chain reaction (RT-PCR) [1], while ZIKV RNA was detectable for two independent RT-PCR targets in plasma and urine [2], confirming ZIKV disease. The patient agreed to follow-up sampling and ZIKV testing of blood, saliva, urine and semen until the sample type turned negative. Additional urine was collected and found positive for the most sensitive target at 6, 10, 13 and 19 days post onset of illness (dpi) (Figure).

Real-time RT-PCR analysis was validated according to ISO15189:2012 guidelines, briefly total nucleic acids were purified from 200 µL of plasma, saliva, urine or semen sample and eluted in a final volume of 100 µL using MagNaPure LC total nucleic acid isolation kit and the HP200 protocol (Roche Life Science, Almere the Netherlands). Subsequently, 8 µL of eluate in a final volume of 20 µL was used per reaction. Real-time RT-PCR was performed using the primers and probe set 1086/1162c/1107-FAM developed by Lanciotti et al. [2], and which annealed the most sensitive target mentioned above, and Fast Virus 1-Step Master Mix (Life technologies, Nieuwkerk a/d IJssel, the Netherlands) on a LC480-II (Roche), with 5 min 50 °C, 20 s 95 °C, and 45 cycles of 3 s 95 °C and 30 s 60 °C as thermal profile. The real-time RT-PCR was internally controlled for inhibition by addition of phocine distemper virus [3].

Saliva was collected at 6 and 10 dpi and was only positive at day 6. Additional plasma samples were taken at 6 and 10 dpi and ZIKV genome levels turned undetectable at 10 dpi. Semen was collected at 10, 13, 19, 20, 32, 34, 47 and 62 dpi and turned negative at the last sampling point.

Based on the semi-quantitative real-time RT-PCR data for the different sample types, the ZIKV RNA load appeared to be the highest in semen and remained higher in semen than in urine in the follow-up samples. Both urine and semen increased the window of ZIKV detection in clinical samples of this patient, with up to six-fold for semen vs plasma or saliva, and show
a slow decline versus plasma and saliva in ZIKV RNA levels with time.

Attempts to isolate virus from saliva at 6 dpi and from all the semen and urine samples failed. Enzyme-linked immunosorbent assay (ELISA; Euroimmun, Lübeck, Germany) testing on serum collected at 6 and 10 dpi demonstrated the presence of anti-ZIKV IgM in both samples and seroconversion for anti-ZIKV IgG. Virus neutralisation using a ZIKV isolate from Suriname gave a reciprocal neutralising antibody titre of 256 at 47 dpi. In line with a report by Mansuy et al. [7], our data show higher ZIKV RNA loads in semen than in other sample types for our patient. Moreover in our study, the viral RNA loads in semen only slowly declined with time to undetectable levels at 62 dpi. Based on this observation and that of others, whereby another study reports RNA loads in semen only slowly declined with time to undetectable levels at 62 dpi. Based on this observation and that of others, whereby another study reports an important implication of the teratogenicity of ZIKV and semen as source for ZIKV infection [13], is the necessity for protected sexual intercourse at least during pregnancy for men returning from ZIKV endemic areas or when residing in those areas. The European Centre for Disease prevention and Control (ECDC) recommends that male travellers returning from areas with active transmission should consider using a condom with a pregnant partner until the end of pregnancy, but should consider the use of a condom for at least one month upon return to reduce the potential risk of onward sexual transmission with non-pregnant female or male partners [14]. Some national guidelines [15-17] advise condom use for one to two months probably based on the very limited ZIKV isolation data that has been reported for semen up to 24 dpi [7,10].

In line with a report by Mansuy et al. [7], our data show higher ZIKV RNA loads in semen than in other sample types for our patient. Moreover in our study, the viral RNA loads in semen only slowly declined with time to undetectable levels at 62 dpi. Based on this observation and that of others, whereby another study reports a patient’s semen still positive for ZIKV RNA 62 dpi, however, with no end-point determination [12], the advice to use a condom with a non-pregnant partner for one month after return from an endemic area might be reconsidered to at least 90 days upon return (including the 62 days [12] and the subsequent maximum incubation time of 13 days [18]) as long as some of the crucial questions mentioned above have not been answered and a fully evidence-based recommendation on condom use is not possible yet. Another implication is the need for review of inclusion criteria for sperm donation.

The higher ZIKV RNA load in semen than in urine samples taken at the same time points found here, has also been previously observed for two other patients [7,10].

**Discussion**

*Aedes aegypti* mosquitoes are the main vector for ZIKV transmission. However, the increasing import of ZIKV cases in non-endemic countries has put a previously obscure mode of non-mosquito-borne ZIKV transmission in the limelight: sexual transmission through infectious semen [7,8]. An increasing number of cases describing sexual transmission of ZIKV from symptomatic men-to-women or from symptomatic men-to-men have been reported from areas where *Aedes aegypti* is not present, including Europe [7,9-11]. Although sexual transmission seems to represent the greatest risk for ZIKV transmission in areas without competent mosquito vectors, little is known about the prevalence of ZIKV in semen of symptomatic and asymptomatic infected men, the kinetics of infectious ZIKV and ZIKV RNA in semen in both of these groups, the possible gonadotropism of ZIKV in men and the minimal infectious dose for semen-borne transmission to men and women. Single time point sampling of semen reported the presence of viral RNA at 14 [7], 27 and 62 dpi [12] and isolation of virus 18 and 24 dpi [10].

An important implication of the teratogenicity of ZIKV and semen as source for ZIKV infection [13], is the necessity for protected sexual intercourse at least during pregnancy for men returning from ZIKV endemic areas or when residing in those areas. The European Centre for Disease prevention and Control (ECDC) recommends that male travellers returning from areas with active transmission should consider using a condom with a pregnant partner until the end of pregnancy, but should consider the use of a condom for at least one month upon return to reduce the potential risk of onward sexual transmission with non-pregnant female or male partners [14]. Some national guidelines [15-17] advise condom use for one to two months probably based on the very limited ZIKV isolation data that has been reported for semen up to 24 dpi [7,10].

In line with a report by Mansuy et al. [7], our data show higher ZIKV RNA loads in semen than in other sample types for our patient. Moreover in our study, the viral RNA loads in semen only slowly declined with time to undetectable levels at 62 dpi. Based on this observation and that of others, whereby another study reports a patient’s semen still positive for ZIKV RNA 62 dpi, however, with no end-point determination [12], the advice to use a condom with a non-pregnant partner for one month after return from an endemic area might be reconsidered to at least 90 days upon return (including the 62 days [12] and the subsequent maximum incubation time of 13 days [18]) as long as some of the crucial questions mentioned above have not been answered and a fully evidence-based recommendation on condom use is not possible yet. Another implication is the need for review of inclusion criteria for sperm donation.

The higher ZIKV RNA load in semen than in urine samples taken at the same time points found here, has also been previously observed for two other patients [7,10].
Conclusions

We describe the longitudinal follow-up of the presence of ZIKV RNA in semen and other sample types in a returning traveller. Semi-quantitative ZIKV RNA levels were consistently higher in semen than in urine in the convalescent phase and slowly declined to an undetectable level at 62 dpi. Testing of semen could have an added value to testing of urine and semen in men up to 2 months dpi.

Acknowledgements

We are grateful to the patient for his willingness to provide additional samples for the study. We thank the team of the Clinical Virology unit for excellent technical support.

The patient provided written informed consent to participate in the study and for publication of this case-report.

Conflict of interest

None declared.
